A Document Expansion Framework for Tag-based Image Retrieval

Abstract

Purpose: The purpose of this paper is to utilize document expansion techniques for improving image representation and retrieval. This paper proposes a concise framework for tag-based image retrieval.

Design/methodology/approach: The proposed approach includes three core components: 1) A strategy of selecting expansion (similar) images from the whole corpus (e.g., cluster-based or nearest neighbor-based). 2) A technique for assessing image similarity, which is adopted for selecting expansion images (text, image or mixed). 3) A model for matching the expanded image representation with the search query (merging or separate).

Findings: Applying the proposed method yields significant improvements in effectiveness. The method obtains better performance on the top of the rank and makes a great improvement on some topics with zero scores in the baseline. Moreover, nearest neighbor-based expansion strategy outperforms the cluster-based expansion strategy, using image-features for selecting expansion images are better than using text features in most cases, and the separate method for calculating the augmented probability $P(q|R_D)$ is able to erase the negative influences of error images in R_D.

Research limitations/implications: Despite our methods only outperform on the top of the rank instead of the entire rank list, tag-based image retrieval on mobile platforms still can benefit from our approach.

Originality/value: Unlike former approaches, the approach proposed by this paper address sparsity, vocabulary mismatch and tag-relatedness in tag-based image retrieval all at once. It is a comprehensive investigation of document expansion techniques in tag-based image retrieval.

Keywords: document expansion; tag-based image retrieval; social image representation; information retrieval; vocabulary mismatch; sparsity; tag-relatedness

Article Classification: Research paper

INTRODUCTION

The development of digital photography and social media-sharing platforms (e.g., Flickr and Instagram) has led to a rapid increase in the number of social images produced. Social bookmarks (tags) provide noisy, yet useful descriptive information to enhance traditional image retrieval technology (Firan et al., 2007; Nov et al., 2008; Sun et al., 2011b). Techniques leveraging social bookmarks for image search are called tag-based image retrieval (TBIR), which have attracted wide attention (Chen et al., 2010; Gao et al., 2013; Li et al., 2015; Li and Snoek, 2010). These approaches are general methods for assessing the similarity between a search query and an image's tags.

Previous studies showed that social tags are usually helpful for image retrieval (Chen et al., 2010; Gu et al., 2011; Liu et al., 2009; Sun and Bhowmick, 2008; Tang et al., 2009). However, a social image usually only has a limited number of tags. For example, in the NUS-WIDE dataset (an open dataset for TBIR), each image has only 18 tags on average, and almost 15% of images own less than 8 tags. Such a tag-based image representation often suffers from serious sparsity and vocabulary mismatch issues. In addition, most image-sharing platforms do not allow users to assign the same tag multiple times, which makes it difficult to distinguish informative tags from less important ones by their frequencies. Therefore, measuring the degree of effectiveness of a tag describing the tagged image also becomes a crucial issue (this we refer to as tag-relatedness issue in this paper). Many studies have been conducted to address these issues. More concretely, neighbor voting schemes (Truong et al., 2012) are widely adopted to measure the degree of effectiveness of a tag describing the tagged image. Tag recommendation (Sun et al., 2011a) and tag completion (Wu et al., 2013) are both put forward in addressing issues of sparsity and vocabulary mismatch. However, it is still very hard to combine these methods into a uniform framework. In this paper, we propose a concise framework based on document expansion techniques widely adopted in document retrieval to address all

these issues at once. In our approach, we consider the set of tags for an image as a "document" for that image. Specifically, our approach has three core components:

1. A strategy of selecting expansion (similar) images from the whole corpus.
2. A technique for assessing image similarity, which is adopted for selecting expansion images.
3. A model for matching the expanded image representation with the search query.

We describe and evaluate our approach in this paper. We compare it with previous approaches and experiment using different implementations of the three core components. The rest of this paper is organized as follows. In Section 2, we review the related work on TBIR from social tags research, related efforts on image retrieval and research on tag-based retrieval. Section 3 provides a detailed description of the proposed approach. Section 4 introduces the experimental setup and analyzes the results in detail. Section 5 concludes this study.

It is worth noting that TBIR is quite different from concept-based (i.e., text-based) image retrieval, because of some characteristics of social tags. For example, in concept-based image retrieval, an image is often represented by a textual document that typically has much redundancy of words to convey its semantics. But, in TBIR, an image is represented with many fewer tags with no or minimal redundancy. Moreover, text used in concept-based image retrieval is usually provided by professional indexers, but social tags are assigned by different users having different motivations, different interpretations of the meaning of tags. Thus, traditional techniques of concept-based image retrieval, such as term frequency weighting and document length normalization, do not work well on TBIR.

RELATED WORK

Research on Social Tags in the Search Environment

Much research has examined social tags from the perspective of organization and retrieval. For example, Nov et al. (2008) divided tagging motivation into three categories

Downloaded by Göteborgs Universitet At 13:15 13 January 2018 (PT)

based on target audience and tagging function into two dimensions based on a tag's intended use. They pointed out that the organization function of tags is intended to facilitate future search and retrieval by the user. Carman et al. (2008) found that social tags (bookmarks) are useful for approximating actual user-queries from the perspective of personalized information retrieval. Gu et al. (2011) concluded that social tags reveal confidence issues caused by ambiguity and synonymy. They proposed a statistic model to measure the confidence of social tags and applied it to filter noisy tags with low tag confidence. The results of their experiment revealed that confidence of social tags highly influenced the performance of tag-based search methods. Wu et al. (2013) stated that, "since many users tend to choose general and ambiguous tags in order to minimize their efforts in choosing appropriate words, tags that are specific to the visual content of images tend to be missing or noisy."

Additionally, Koutrika et al. (2008) asserted that misleading tags confuse users instead of increasing the visibility of some resource. Therefore, they proposed a method for ranking documents matching a tag based on taggers' reliability. Li et al. (2009) stated that various tagging motivations naturally lead to the personalization characteristic of social tags and create an unreliable interpretation of the relevance of a tag with respect to the visual content that it is describing. Hence, the fundamental problem in tag-based image retrieval is how to reliably estimate the relevance of a tag with respect to the visual content that it is describing. Note that the above characteristics of social tags make TBIR more challenging than concept-based image retrieval, and demand a revisit rather than directly employing techniques of concept-based image retrieval (Sun et al., 2011b).

Related Efforts on Image Retrieval

Inspired by research on text-information retrieval, many methods (sometimes called text-based image retrieval) have been developed to improve image search in cases in which textual descriptions of visual content are vague (La Cascia et al., 1998; Sclaroff et al., 1999). However, considering the problem of subjectivity in contextual information,

Downloaded by Göteborgs Universitet At 13:15 13 January 2018 (PT)

This is a pre-print of a paper and is subject to change before publication. This pre-print is made available with the understanding that it will not be reproduced or stored in a retrieval system without the permission of Emerald Publishing Limited.

text-based image retrieval also possesses some limitations (Inoue, 2004). To overcome the problem in text-based image retrieval, many efforts (often termed Content-based Image Retrieval, CBIR) attempt to utilize visual content for estimating image visual similarity (Gudivada and Raghavan, 1995; Smeulders et al., 2000). One primary goal of these studies is to measure the similarity between two images based on their level features (color, texture, shape) and semantic content (object, scene, emotion).

More recently, advancements in image understanding, such as image classification and object recognition, have made it possible to learn and understand visual concepts from images (Krizhevsky et al., 2012; Torralba et al., 2008). For example, automatic image-annotation focuses on assigning a few relevant and controlled keywords to an un-annotated image, and then these keywords can be indexed and utilized for image retrieval. Jeon et al. (2003) proposed a cross-media retrieval model for annotating images with keywords from a small vocabulary of blobs[1], and their experiment demonstrates the usefulness of these keywords for the task of image retrieval.

Research on Tag-based Retrieval

On the other hand, with the popularity of folksonomy, uncontrolled and personalized social tags as meta-data, we see new opportunities to enhance current retrieval technology. Bao et al. (2007) proposed two algorithms that use social tags for web search, and they found that social tags are usually good summaries of corresponding web pages and the count of tags indicates the popularity of web pages. Xu et al. (2008) proposed a personalized search framework to utilize folksonomy (social tags) for personalized web search. Melenhorst et al. (2008) reported a study on tag-based video retrieval, and their experiment suggested that uncontrolled social tags are valuable for supporting video retrieval processes. Hsieh and Hsu (2010) proposed a method to annotate images with social tags, their method is able to solve the sparsity of user-contributed tags. Sevil et al. (2010) presented an automatic tag expansion approach, which is valuable for image retrieval. Efron (2010) proposed a language-modeling

approach to retrieve useful hashtags from posts in a microblogging environment. Inspired by document expansion and inverted index in traditional IR, Min et al. (2010) revisited document expansion in the context of retrieval of images annotated with brief textual labels. Zhu et al. (2010) and Sang et al. (2012) introduced the task of tag refinement which aims to solve the imprecise and incomplete issues of social tags. Lee et al. (2012) proposed a social inverted index for social-tagging-based IR. Li and Snoek (2013) developed a system that has the ability to select the most relevant positive and negative examples for a given tag. Recently, Li et al. (2016) presented a comprehensive treatise about image tag assignment, refinement, and tag-based image retrieval. Lu et al. (2016) proposed an re-ranking approach depending on three steps: the first step "Keyword matching" returns all images that contain the query terms and the images uploaded by the same user, grouped into user image set; then the second step "Inter-user re-ranking" ranks user image sets by considering users' contributions to the query; finally the third step "Intra-user re-ranking" select the image which has the highest score among each user image sets. A state-of-the-art research in TBIR has been performed by Sun et al. (2011b), which quantifies the relevance score between a tagged image and a tag query by five orthogonal dimensions:

(i) *Tag discrimination*, analogous to the idea of tf-idf in traditional IR;

(ii) *Tag length*, used to reflect the impact of the number of tags assigned to social images;

(iii) *Tag-query matching score*, quantifying the matching score between a tag and the query tag t_q;

(iv) *Query model*, used for rewriting a given query, analogous to query expansion technology in traditional IR;

(v) *Tag-relatedness*, used to measure the degree of effectiveness of a tag describing the tagged image.

DOCUMENT EXPANSION APPROACH

Task Definition

Our approach addresses the tag-based image retrieval (TBIR) problem. Tag-based image retrieval refers to an image retrieval task where the images often have user-generated short text descriptions (tags). A tag is usually a single word, but can be more complex, e.g., "xmas2015". However, our approach does not consider the latter case because the majority of the tags in our dataset belong to the first case—a tag is considered as one word token in this paper.

Tag-based image retrieval has been widely applied on image-sharing platforms in different scenarios to help users look for images. For example, the famous image-sharing website flickr.com provides two kinds of tag-based image retrieval. First, users can type a text query (one or a few words) in the search bar to find relevant images annotated by other persons using similar words (social tags). Second, while browsing images, users can click on the social tags associated with the images, and the system will retrieve relevant images using the clicked tag as a query. In this paper, we only consider the second scenario.

We formally define the TBIR problem as follows. The corpus is a collection of N social images $C = \{D_1 \ldots D_N\}$, where each image D_k is associated with a set of m tags $\{w_{k1}, w_{k2}, \ldots, w_{km}\}$. Given a query q containing s words (tags) $\{w_1, \ldots, w_S\}$, the task is to rank images by their relevance to the query.

Tag-based image retrieval techniques focus on improving retrieval accuracy using tag information. We can consider the set of tags for an image as a complementary representation for that image, in addition to other representations such as its content.

Specifically, we adapt document expansion techniques for the TBIR problem to address the vocabulary mismatch issue in tag-based image retrieval. Here we consider the set of tags for an image as a "document" for that image. As Sun et al. (2011b) pointed out, the tag-based image representation (document) suffers from sparsity issues, i.e., an image is usually associated with only a few tags. This makes a query difficult to match a relevant image if they used similar but different words. In addition, most image-sharing

platforms do not allow users to assign the same tag multiple times, which makes it difficult to distinguish informative tags from less important ones by their frequencies. This is also similar to the issue of lacking term frequency information in short-text retrieval (Efron et al., 2012). Both issues increase the risk of vocabulary mismatch when using tag-based representation for image retrieval.

The rest of this section describes our approach.

Framework

Our system ranks a target image by the following steps:

1. We find images similar to the target image.
2. We compute a relevance score for the target image based on the similarity of the query to the target image itself as well as its similar images.
3. We rank target images by the computed relevance scores.

Figure 1 shows an example. The target image has two tags *sky* and *helicopter*, while the query includes a word *blue* that does not exist in the target image's tag-based representation. Apparently, the target image is relevant, but it has a relatively low relevance score if we directly match the query with the target image's tags. Instead, our approach expands the target image's tag-based representation using similar images. For example, if a similar image has the tags *blue*, *sky*, and *cloud*, it improves the target image's representation by helping it to match the word *blue* in the query (and hopefully enhances retrieval performance).

Formally, we use D for the original (unexpanded) tag-based representations for an image. We use R_D for D's augmented representation based on similar images' tags. We rank images using Equation (1). The parameter α_{exp} controls the weight of the expanded representation.

$$Score(q, D) = (1 - \alpha_{exp}) \cdot P(q|D) + \alpha_{exp} \cdot P(q|R_D) \ldots\ldots (1)$$

The rest of this section introduces:

1. The strategies of selecting similar images – we compare a cluster-based strategy and a nearest neighbor-based one.
2. The techniques used for assessing image similarity (in order to select similar images in Step 1) – we compare using image content, tags, and a combination of the two to assess image similarity.
3. Matching the query q and the expanded image representation R_D, i.e., estimating $P(q|R_D)$ – we compare two approaches.

Document Expansion Strategy

Inspired by previous studies on document expansion (Liu and Croft, 2004; Tao et al., 2006; Wei and Croft, 2006), we compare two document expansion strategies for selecting similar images:

- **Cluster-based strategy**: We group images into clusters and select the closest cluster to the target image for expansion. We use K-means algorithm for clustering. For each image D, its expansion image set $R_D = \{D_1, D_2, \ldots, D_M\}$ consists of all images sharing the same cluster with D.
- **Nearest Neighbor strategy**: The nearest neighbor strategy selects the most similar k images to the target image for expansion. We construct a pseudo-query Q_D based on the target image's representation and retrieve the top k similar images. The expansion image set $R_D = \{D_1, D_2, \ldots, D_k\}$ consists of the top k similar (relevant) images retrieved for Q_D, where each image is associated with a similarity score.

© Emerald Publishing Limited
This is a pre-print of a paper and is subject to change before publication. This pre-print is made available with the understanding that it will not be reproduced or stored in a retrieval system without the permission of Emerald Publishing Limited.

The intuition behind these two expansion strategies is quite different. The cluster-based method assumes that different images in the same cluster belong to the same topic (Liu and Croft, 2004). It does not differentiate images in the same cluster while performing expansion—each expansion image has an equal weight in R_D. In contrast, the nearest neighbor strategy specifically retrieves the most similar k images for the target image for expansion. Different images are assigned different weights—their relevance scores. It assumes that more similar images provide better complementary representations for the original image (Tao et al., 2006).

Downloaded by Göteborgs Universitet At 13:15 13 January 2018 (PT)

Image Similarity

Both the cluster-based and the nearest neighbor-based expansion strategy require techniques for assessing image similarity. We compare three different ways of assessing image similarity in this paper.

(1) Text/tag-based approach – assessing image similarity only based on tag-based representation.

- While using the cluster-based strategy, we represent each image as a vector of tags, and cluster images using K-means algorithm with cosine distance.
- While using the nearest neighbor strategy, we construct a text query for the target image using the combination of its tags. We submit the query to a text retrieval IR system (such as Indri or Lucene) to obtain a ranked list of relevant (similar) images. We set the weights of the images to their relevance scores returned by the text IR system while performing expansion.

(2) Image feature-based approach – assessing image similarity only based on image content.

- While using the cluster-based strategy, we represent each image's visual features using a 500-dimension bag of "words" feature based on SIFT (scale-invariant feature transform) descriptions (Kulis and Grauman, 2009). We also use K-means algorithm with cosine distance for clustering. Although there are various

© Emerald Publishing Limited
This is a pre-print of a paper and is subject to change before publication. This pre-print is made available with the understanding that it will not be reproduced or stored in a retrieval system without the permission of Emerald Publishing Limited.

visual features for representing image content, it is beyond the scope of this paper.

- While using the nearest neighbor strategy, we use the image's visual feature as a query to retrieve similar images in a content-based image retrieval system. We retrieve images using LSH (Locality Sensitive Hashing) (Jégou et al., 2010) and cosine distance. Although there are various approximate nearest neighbor methods for searching *k* nearest neighbor images and measuring image similarity based on visual features, it is beyond the scope of this paper.

(3) Mixed feature-based approach – assessing image similarity based on the combination of tag-based representation and image content.

- While using the cluster-based strategy, we construct a mixed representation for each image by concatenating its text feature vector and visual feature vector. Then, we use K-means algorithm with cosine distance for clustering.
- While using the nearest neighbor strategy, we combine the lists of similar images retrieved using the tag-based approach and the image feature-based approach using CombMNZ, a popular method for fusing ranked lists (Fox and Shaw, 1994). Equation (2) explains the score of an image D_i by CombMNZ, where: $F(D_i)$ refers to the number of times the image D_i appeared in the two ranked lists; $S_{text}(D_i)$ and $S_{image}(D_i)$ are the scores returned by the text IR system and CBIR system, respectively.

$$S_{combMNZ}(D_i) = F(D_i)*(S_{text}(D_i) + S_{image}(D_i)) \quad \ldots\ldots (2)$$

Matching Queries and Expanded Image Representation

Let $R_D = \{D_1, D_2, \ldots, D_M\}$ be the set of expansion images selected using the approaches described in the previous sections. Each D_i in R_D is associated with a weight—the importance of D_i in expansion. While using the cluster-based strategy, the weight of each image is set to 1. The weight of an image is set to its relevance score if we adopt the nearest neighbor strategy for image expansion.

Downloaded by Göteborgs Universitet At 13:15 13 January 2018 (PT)

© Emerald Publishing Limited
This is a pre-print of a paper and is subject to change before publication. This pre-print is made available with the understanding that it will not be reproduced or stored in a retrieval system without the permission of Emerald Publishing Limited.

We compare two methods for computing the probability of a query q given R_D:

- ***"Merging"***. In this approach, we merge all "documents" (images' tag sets) in R_D as a big "document" D'. Thus, the probability $P(q|R_D)$ can be estimated as in Equation (3), where $D' = \{t_1, t_2, \ldots, t_L\}$ is the bag of tags associated with the image set $R_D = \{D_1, D_2, \ldots, D_M\}$. L is the total number of unique tags in the image set R_D. sim(D, Dj) stands for the weight of the image Dj in the expansion set. S is the number of words (tags) in query q.

$$P(q|R_D) = P(q|D') = P(q|t_1, t_2, \ldots, t_L) = \sum_{i=1}^{S} P(w_i|t_1, t_2, \ldots, t_L)$$
$$= \sum_{i=1}^{S} \frac{\sum_{j=1}^{M} freq(w_i, D_j)\, sim(D, D_j)}{\sum_{l=1}^{L}\sum_{j=1}^{M} freq(t_l, D_j) \cdot sim(D, D_j))} \ldots\ldots (3)$$

- ***"Separate".*** In this approach, we compute the probability $P(q|R_D)$ by marginalizing over all documents in R_D. We sum over the probability of q from each individual document D_i, weighted by D_i's weight in the expansion set. Equation (4) describes this approach.

$$P(q|R_D) = \sum_{D_i \in R_D} P(q|D_i) Sim(D, D_i) \ldots\ldots (4)$$

EXPERIMENT

The NUS-WIDE dataset is an open and accessible benchmark for evaluating tag-based image retrieval techniques released by the National University of Singapore. The dataset incorporates 269,648 images acquired from Flickr[2] and 81 queries. We also test our methods on the Flickr51 dataset, a smaller dataset containing 81,541 images and 51 queries. All these queries are simple concepts such as "airport", "valley", etc. We refer to the literature (Chua et al., 2009; Wang et al., 2010) for further details.

We compare with two baselines: a language modeling approach (LM) and Sun et al.'s (2011b) approach (the $Q_S R_V D_F L_S M_C$ model with the 500-dimension bag of "words" feature based on SIFT descriptions). The LM baseline simply treats the set of tags for an image as a document and ranks images by the query likelihood score. We stem words using the Krovetz stemmer. We report results using Jelinek-Mercer smoothing with λ =

Downloaded by Göteborgs Universitet At 13:15 13 January 2018 (PT)

© Emerald Publishing Limited
This is a pre-print of a paper and is subject to change before publication. This pre-print is made available with the understanding that it will not be reproduced or stored in a retrieval system without the permission of Emerald Publishing Limited.

0.4. Based on our observation, smoothing has very little impact on the search results in this dataset. Sun et al.'s approach ($Q_S R_V D_F L_S M_C$) quantifies the relevance score between a tagged image D and a query q as in Equation (5), where $N_k(D)$ is the 100 similar images for image D based on visual similarity (500-dimension bag of "words" feature); t_j is one of the tags belong to image D; $P(t_j|N_k(D))$ and $P(t_j)$ are the probabilities of observing tag t_j among images in $N_k(D)$ and collection C, respectively; N is number of images in collection C; $f(t_j)$ is the number of images annotated by tag t_j in collection C; $|D|$ is the number of tags of image D; $P(t_j|w_i)$ is the conditional probability of being tagged by t_j among the images tagged by w_i in collection C.

$$Score(q,D) = \sum_{w_i \in q, t_j \in D} \left(0.5 + 0.5 * max\left(P\left(t_j \middle| N_k(D)\right) - P\left(t_j\right), 0\right)\right) * \left(1.0 + log\frac{\mathrm{N}}{1 + f\left(t_j\right)}\right) * \frac{1}{\sqrt{|D|}} * P(t_j | w_i) \quad \ldots\ldots (5)$$

For the cluster-based strategy on NUS-WIDE, we use cluster size 500, 1000, 2000 and 3000. Due to the scale of Flickr51 is much smaller than (one-third of) NUS-WIDE, we choose cluster size 160, 330, 660, 1000 while we conduct experiments on the Flickr51 dataset. For the nearest neighbor strategy on two datasets, we compare using the top 10, 20, 50 and 100 similar images for expansion. We evaluate results using four metrics including: (i) mean average precision (MAP), the mean of average precision for a sample of queries, where average precision is a measure that combines recall and precision for ranked retrieval results; (ii) mean reciprocal rank (MRR), the average of reciprocal ranks for a sample of queries, where the reciprocal rank is the multiplicative inverse of the rank of the first correct answer; (iii) precision at 10 (P@10), a statistic measure that counting the number of relevant results on the top 10 results; (iv) normalized discounted cumulative gain at 10 (nDCG@10), a measure of ranking quality that considers cumulative gain at each position of ranking list; we refer to the literature (Sanderson, 2010) for further details. We evaluate all methods using five-fold cross-validation. We train the best parameters (smooth parameter α, cluster size L, the number of similar images k) by performing a grid search. We compare the two approaches by the mean

RESULTS AND DISCUSSION

Table 2 reports the evaluation results. Comparing the two baselines, we found that $Q_SR_VD_FL_SM_C$ outperforms LM on both NUS-WIDE and Flickr51 datasets. The limited performance of LM in TBIR is not surprising. LM ranks result mainly based on term frequency and document length. In the case of TBIR, tag (term) frequency is always 1, because many current systems do not allow assigning the same tag to the same image multiple times. Thus, the score is very sensitive to the number of tags associated with the image (document length). This means that LM, in the case of TBIR, will find images which contain the query term (tag) and rank the images by document length (the number of tags associated with that image). In contrast, the $Q_SR_VD_FL_SM_C$ model, estimating the relevance between the tag and visual content of the image by nearest-neighbor-voting, seems to overcome the problem in the LM method.

Our approach uses "document" expansion techniques to improve image representation. It achieves better results in terms of all evaluation measures compared to the two baselines. We think that document expansion enhances the presentation of images in two ways: (1) Assigning the right and unannotated tags to the image. (2) Increasing the weight of the right tags of the image. Figure 2 shows an instance of the situation. The left one is an original document D and the right one is one of the images in R_D. Under the framework of document expansion, the weight of "sky", "clouds", and "helicopter" will increase and an unannotated right tag "blue" will be assigned to the left image, then the left image can be retrieved by the query "blue".

Next, we will focus on discussing the differences in document expansion strategies, information modality for selection of R_D and computation methods of the augmented probability $P(q|R_D)$.

Comparing document expansion strategies

We compare the cluster-based document expansion strategy and the nearest neighbor strategy in this section. Table 3 reports the evaluation results for the best cluster-based strategy run (M4) and the best nearest neighbor strategy run (M10) on two datasets. Results show that both document expansion strategies are at least as good as the baseline. As Table 3 shows, the cluster-based strategy run performs as good as $Q_SR_VD_FL_SM_C$ in terms of MRR (+2.1%). P@10 (+0.4%) and nDCG@10 (+1.4%) on NUS-WIDE, and brings significant[3] improvements in P@10 (+8.1%. $p<0.05$) and nDCG@10 (+5.4%. $p<0.05$) on Flickr51. In contrast, the nearest neighbor-based strategy significantly outperforms the $Q_SR_VD_FL_SM_C$ baseline in all terms of both P@10 (+7.2%. $p<0.05$) and nDCG@10 (+5.8%. $p<0.05$) on NUS-WIDE, and brings significantly improvements in MAP (+7.7%. $p<0.05$), MRR (+10.3%. $p<0.05$), P@10 (+12.0%. $p<0.05$) and nDCG@10 (+18.7%. $p<0.05$). Note that we did not see stable improvements in terms of MAP and MRR on the two datasets but in P@10 and nDCG@10.

Figure 3 – An illustration of why nearest neighbor-based strategy is better than cluster-based strategy.

In addition, results also suggest that the nearest neighbor-based strategy is better than the cluster-based one. This is probably because the cluster-based strategy introduces too much noise—it is over-optimistic to assume that images in the same cluster contribute the same to the expanded representation. In contrast, the nearest neighbor-based strategy overcomes this issue by weighting images differently during expansion. Figure 3 shows an example. Although both strategies expanded the wrong image Dj, in nearest neighbor-based strategy the sim(D, Dj) is 0.35, much less than 1 in cluster-based strategy.

Comparing approaches for assessing image similarity

We compare the three approaches for assessing image similarity (text, image, or mixed) in this section.

Table 4 lists the average scores of different measures for runs using the text-based approach, the image-based approach, and the mixed approach. Figure 4 shows detailed results using different combinations of document expansion strategy and matching model. Results suggest that using image-features for selecting expansion images is better than using text features in most cases. In addition, using mixed features does not outperform using text or image features alone.

Table 4 – Average scores of three information modalities.

NUS-WIDE				
Information Modality	**MAP**	**MRR**	**P@10**	**nDCG@10**

Text (mean of M1+M2+M7+M8)	0.5959	0.7310	0.6339	0.5056
Image (mean of M3+M4+M9+M10)	**0.7639**	**0.8722**	**0.8456**	**0.7431**
Mixed (mean of M5+M6+M11+M12)	0.6082	0.6496	0.5985	0.4855

We suspect the sparsity issue of text/tag-based representation is a key reason for its limited performance in terms of assessing image similarity. In contrast, in such a case, using image features is usually a better option. Figure 4 shows an example. Of course, the text/tag-based representation makes it much easier to connect images and search queries. Thus, our approach is also an effective way of combining text/tag-based and content-based image retrieval—we leverage low-level image features to connect similar images and improve images' text/tag-based representation. It is worthy to note that mixed-features do not demonstrate the advantage that had been expected. In the cluster-based approach, the mixed feature suffers from the curse of dimensionality. In the nearest neighbor-based strategy, the set of images expanded with image representation is quite different from the set of images expanded with tag-based representation. Therefore, the CombMNZ method fails to utilize images appeared in both two sets.

Matching queries and expanded image representation

We compare the two different approaches for computing $P(q|R_D)$ in this section – "merging" and "separate". Table 5 reports the differences between the two computation methods using different combinations of expansion strategy and image similarity

© Emerald Publishing Limited
This is a pre-print of a paper and is subject to change before publication. This pre-print is made available with the understanding that it will not be reproduced or stored in a retrieval system without the permission of Emerald Publishing Limited.

measures. Overall, results suggest that the "separate" approach is better than the "merging" approach when computing $P(q|R_D)$.

We suspect the "separate" approach works better than the "merging" approach because the former is less likely affected by wrong expansion images with a lot of tags. While using the "merging" approach, an expansion image with a lot of tags will increase both tags' frequencies and document length of the merged "big document" representation by a greater extent. This may be useful if the expansion image is truly relevant to the original image, but it also introduces more noise when the expansion image is not relevant. In contrast, the "separate" approach does not have the issue.

Influence of cluster-size and number of top k nearest neighbors

In cluster-based methods, cluster size has an impact on retrieval performance. In neighborhood-based methods, the parameter *k* (the number of top similar images) also has an important influence on retrieval performance. Thus, in this section, we discuss how these two parameters influence retrieval performance. In comparison to baselines,

© Emerald Publishing Limited
This is a pre-print of a paper and is subject to change before publication. This pre-print is made available with the understanding that it will not be reproduced or stored in a retrieval system without the permission of Emerald Publishing Limited.

our methods do not bring consistent improvements in terms of MAP but in terms of P@10 and nDCG@10. This suggests our methods have the ability to obtain better performance on the top of the rank. Therefore, in this section, we focus on how cluster size *L* and number of similar images *k* influence on P@10 and nDCG@10.

Figure 5 shows retrieval performance of the cluster-based methods using different cluster sizes. Although we did not observe any clear trends, most methods achieved excellent scores when setting cluster size to 3000 (1000 on Flickr51). Figure 6 shows retrieval performance of the nearest neighbor method with a different number of top similar images *k*. It seems that in general the nearest neighbor method prefers using more results for expansion, except in the case of NN+mixed+merging (M11) on NUS-WIDE and NN+text+separate (M8) on Flickr51.

Insert Figure5 Here

Figure 5 – Influences of the cluster size CL

Insert Figure6 Here

Figure 6 – Influences of the number of similar images k

This suggests that for both expansion strategies, the parameter settings are not trivial and will influence the system's performance. We also suggest to fully train these parameters before deploying our techniques to a practical scenario.

The weight of the expanded representation

© Emerald Publishing Limited
This is a pre-print of a paper and is subject to change before publication. This pre-print is made available with the understanding that it will not be reproduced or stored in a retrieval system without the permission of Emerald Publishing Limited.

The weight of the expanded representation also affects the retrieval performance. Figure 7 shows the three measures' values for NN+image+separate (M10, the best performing run) with different values of α_{exp}. It is clear that all measures' values increase substantially when α increases from 0.1 to 0.5. The trend of increasing becomes smooth when $\alpha>0.5$.

Results show the optimal performance is usually achieved when using a higher weight on the expanded representation compared with the original image representation ($\alpha>0.5$). This indicates the important role of the expanded representation in helping the original tag-based representation to achieve high retrieval performance.

Downloaded by Göteborgs Universitet At 13:15 13 January 2018 (PT)

Insert Figure7 Here

Figure 7 – Performance of smoothing parameter α_{exp}. The x-axis indicates α_{exp}, the y-axis indicates the number of P@10 or nDCG@10.

Per-topic difference

In addition, it is noteworthy that the retrieval performance gains a significant and comprehensive improvement comparing with $Q_S R_V D_F L_S M_C$ (B2) when we use NN-image-separate method (M10) and set *k* at 100 for document expansion (Table 6). We also examine per-topic performance.

Figure 8 shows the difference of nDCG@10 between $Q_S R_V D_F L_S M_C$ model and the NN-image-separate method (*k* at 100) on a query-by-query basis. We found that more than 40% of query topics benefit from our methods on both datasets. On the NUS-WIDE dataset, half of the query topics in the right-most panel increase over 0.25, and almost all query topics in the left-most panel decrease within 0.25. On the Flickr51 dataset, lots of query topics in the right-most panel increase over 0.2. It is interesting to note that our method makes a great improvement on some topics with zero scores in the baseline (the circle-shaped markers at the x-axis). Overall, the improvement on nDCG@10 means that

© Emerald Publishing Limited
This is a pre-print of a paper and is subject to change before publication. This pre-print is made available with the understanding that it will not be reproduced or stored in a retrieval system without the permission of Emerald Publishing Limited.

our method succeeds in bringing relevant images to the top 10. Although our methods don't stable outperform in terms of MAP, they bring improvements on top ranks. Thus, the method will benefit a special scenario where users may pay more attention to top results, e.g., enjoying a tag-based image retrieval service in the mobile platform.

Table 6 – Comparison between $Q_S R_V D_F L_S M_C$ and NN-image-separate (M10) method (k=100). The *symbol indicates $p < 0.05$ on a two pair-wise tests against the baseline.

indicated that the individual method is able to erase the negative influences of error images in R_D. In addition, we also found that mixed features do not demonstrate the advantage that had been expected.

Computation cost

Despite its high performance, a practical concern for the nearest-neighbor strategy is the cost of finding and computing expansion images. For example, if we simply re-rank the top N images retrieved by an initial approach (such as a baseline), we need to expand each of the top N images—while using the nearest neighbor strategy, this means N additional k nearest neighbor search. In contrast, the cluster-based strategy is usually cheaper at running time as long as we pre-compute and store the clustering result. However, it cannot handle dynamic dataset—when the collection changes, we need to re-cluster the whole collection.

We report time cost for the bigger dataset (NUS-WIDE) used in our experiments. Table 7 shows the time cost of the two expansion strategies on a computer with Intel(R) Xeon(R) E5-2640 v2 @ 2.00GHz CPU. On average, a k nearest neighbor search using image features only takes 5.5 milliseconds—this means that it takes less than 1s in the dataset to expand and re-rank a list of 100 images, and it takes about 5s to re-rank 1000 images. Despite the increased computation cost, we believe the technique is still reasonably fast, which makes it useful for many occasions requiring high accuracy image search results.

Table 7 – The time cost of clustering and neighborhood-searching.

Abbr.	CL	Time cost
Image-clustering (using scikit-learn mini batch k-means algorithm[4])	500	115.89s
	1000	160.01s

Text-neighborhood-searching (using Indri to find similar images for per document in corpus)		0.065s

CONCLUSION

In this paper, we propose a concise framework based on document expansion techniques to address the sparsity, vocabulary mismatch and tag-relatedness issues in tag-based image retrieval. We experimented and compared different strategies, similarity measures, and models for constructing expanded image representation.

Unlike the former best performing work based on neighbor voting for pre-computation of tag relatedness, we used document expansion to measure the relation between tags and images. Our method is simple to understand and takes full advantage of the established technology of traditional IR and content-based image retrieval. With respect to the established baseline, the results of our experiments show that applying our NN-image-separate method yields significant improvements in effectiveness. Specifically, our method obtains better performance on the top of the rank and makes a great improvement on some topics with zero scores in the baseline. We also find that the neighborhood-based document expansion strategy outperforms the cluster-based document expansion strategy, mixed-features for the selection of R_D does not demonstrate the advantage that had been expected, and the separate method for calculating the augmented probability $P(q|R_D)$ is able to erase the negative influences of error images in R_D.

More recently, the development of deep-learning has greatly increased the quality of automatic image-annotation and makes it possible to predict multiple textual labels or generate natural language descriptions for an unseen image (Murthy et al., 2015). It

Downloaded by Göteborgs Universitet At 13:15 13 January 2018 (PT)

This is a pre-print of a paper and is subject to change before publication. This pre-print is made available with the understanding that it will not be reproduced or stored in a retrieval system without the permission of Emerald Publishing Limited.

seems that these textual labels or descriptions can be indexed and used for image retrieval directly (Karpathy and Li, 2015). Although these methods create new opportunities to improve the performance of image retrieval, some disadvantages still exist regarding their application to image retrieval. Compared with textual labels and descriptions generated by these costly and time-consuming methods, social tags are easy-to-use and ready-to-use without requiring any additional training data. Moreover, social tags associated with images contain much abstract and personalized information, whereas general automatic image annotation focuses on assigning controlled keywords and limited concepts. So, we think that using social tags for image retrieval still constitutes a good choice in the short-term.

Moreover, it is noteworthy that our approach is independent of any characteristic of social tags. If we use text labels or descriptions generated by automatic image annotation instead of social tags, the proposed method can also be applied to annotation-based image retrieval. We believe that users searching images with the TBIR system will benefit from our method. In future work, we plan to train an effective and suitable model for annotating the images in our dataset and to test our approach on text generated by automatic image annotation methods.

This study has some limitations as well. First, we only consider the scenario that users search for relevant images by clicking on social tags associated with images (single concept query topics). To overcome this limitation, future research may consider multiple concepts query topics. Second, our methods only obtain better performance on the top of the rank instead of the entire ranked list. Therefore, this approach may benefit a special scenario where users may only pay attention to top rank results, e.g., searching on a mobile platform.
